Abstract

Spam, or unsolicited email, is becoming an increasingly large problem as email becomes more and more popular. In this assignment, we discuss various machine learning methods and use them to create spam classifiers. We then analyze the results and effectiveness of these methods. We found that logistic regression is the best method to use for this problem, and AdaBoost is the least preferable.

1 Introduction and background

Email is something used daily by a large number of people. Advertisers and other people trying to sell things have taken advantage of this fact by sending out unsolicited emails, which is referred to as spam. In response to this, spam filters were created to identify these emails and to keep them from clogging up inboxes.

2 Description of data and data processing

The training data set consists of 22,500 spam emails and 22,500 non-spam emails from the trec07p data set. We used the provided script to define a vocabulary create a bag-of-words representation for each email. The resulting vocabulary contained 9579 words. The classifiers are built using these bag-of-words representations as features for the training data. The testing data set consists of 2,500 spam emails and 2,500 non-spam emails from the same corpus, and they are processed in a similar manner to also create bag-of-words representations.

3 Methods

We used the methods implemented in the scikit-learn package. [1]

3.1 Simple methods

1. Naive Bayes classifier, using multinomial implementation
2. Decision tree, using Gini impurity scores and no max tree depth
3. Logistic regression, with l_2 penalty

3.2 Complex methods (ensemble learning)

1. Random forests, with 10 trees and Gini impurity scores
2. AdaBoost, with 50 decision stumps as weak learners

4 Preliminary results

4.1 Simple classifiers

4.1.1 Multinomial naive Bayes

Using this classifier, we predicted labels for the testing data and got an accuracy rate of 98.74%. The ROC curve can be seen in figure 1(a) and indicates a high true positive and low false positive rate. The precision recall curve can be seen in figure 1(b). Curves for our other methods looked extremely similar to these, so they are not included in this report. The full set of ROC and precision-recall curves can be found in the “writeup/images” folder of the GitHub repository for this project. [2]

4.1.2 Decision tree

Training this classifier on all available training data and testing on the provided testing set resulted in an accuracy rate of 99.5%. As the ROC curve is almost identical to that of multinomial naive Bayes, it also has a very high true positive and low false positive rate.

4.1.3 Logistic regression

This method had an 99.75% accuracy. This method also has a very high true positive and low false positive rate.

4.2 Complex classifiers

4.2.1 Random forests

Using this method, we got 99.58% accuracy. This method, like the others, has a very high true positive and low false positive rate. This indicates the high level of correctness of this method.

4.2.2 AdaBoost

AdaBoost had 99.16% accuracy. Like the other methods, it has a very high true positive and low false positive rate. This method also ran extremely slowly compared to our other methods.

4.3 Notes

In an effort to view the data more clearly, we plotted the data on log scales. Specifically, we plotted the x-axis on a log10 scale in order to examine lower false positive rates. However, this did not significantly change the quality of the graph so we decided not to include it in this report.

5 Analysis of results

5.1 Initial results

For each classification method, we used stratified 5-fold cross-validation on the training set of emails. We used the same number of folds across all methods in order to facilitate comparison.

Preliminary comparison of results, described in the previous section, was done using accuracy and ROC curves. We then did further analysis and comparison using precision, recall, and F_1 scores. In figure 2, we can see values for the methods run on both the entire corpus at once and for averages from running 5-fold cross-validation.

There are a few differences between running classifiers on the entire corpus versus doing cross-validation. The most easily explained of these is the time: because cross-validation trains using 4/5 of the available data, it will take less time than training on all the data.

Classifier		Time (s)	Accuracy	Precision	Recall	F_1 score
Naive Bayes	Entire data set	1.51	0.9874	0.9963	0.9784	0.9873
	Cross-validation	1.25	0.9940	0.9984	0.9895	0.9939
Decision Tree	Entire data set	150.0	0.9948	0.9950	0.9936	0.9947
	Cross-validation	106.05	0.9856	0.9956	0.9752	0.9850
Logistic Regr	Entire data set	8.62	0.9974	0.9996	0.9952	0.9974
	Cross-validation	6.08	0.9968	0.9955	0.9981	0.9968
Random Forest	Entire data set	11.46	0.9968	0.9992	0.9944	0.9968
	Cross-validation	8.18	0.9976	0.9969	0.9984	0.9976
AdaBoost	Entire data set	642.94	0.9916	0.9976	0.9856	0.9915
	Cross-validation	482.88	0.9966	0.9970	0.9962	0.9966

5.2 Running time

As we can see in figure 2, using Naive Bayes is by far the fastest of the five methods we used. Logistic regression and random forests perform reasonably well. Decision trees, however, are rather slow. This is due to the fact that we did not constrain the height of the tree. AdaBoost is prohibitively slow; moreover, AdaBoost does not offer any sort of increase in performance with regards to accuracy. It is therefore a suboptimal choice for solving this problem.

5.3 Feature selection results

We tried selection of 5, 10, and 15% of features. Performance among the three was best at the 5% level of selection; we have included these results in figure 3. In comparison to learning on the entire training set, performance on the feature selected set in terms of accuracy, precision, recall, and F_1 decreased slightly. On the other hand, running time also decreased dramatically for most methods.

An exception to the running time decreasing drastically is logistic regression. While its running time decreased after feature selection, it does not scale linearly with the number of features. For example, the running time for naive Bayes dropped from 1.51 to 0.08 seconds (about 5% of its original runtime) after feature selection. In contrast, the running time for logistic regression only dropped from 8.62 to 6.01 (69.7% of its original runtime).

Because the drop in correctness is most likely not as significant as the boost in performance time-wise in most situations, feature-selected training and testing is probably preferable. In situations that require high accuracy/precision, however, using the full feature set would still be better.

5.4 Important features

During feature selection, we selected the “best” 5% of features. Features were ranked by statistical significance, which was found using ANOVA analysis. We looked at the top 20 features according to this analysis, and most of the words appeared to be part of email headers. Some examples include:

Classifier		Time (s)	Accuracy	Precision	Recall	F_1 score
Naive Bayes	Entire data set	0.08	0.9526	0.9752	0.9288	0.9514
	Cross-validation	0.07	0.9629	0.9636	0.9632	0.9630
Decision Tree	Entire data set	2.96	0.9936	0.9952	0.9920	0.9936
	Cross-validation	2.19	0.9925	0.9956	0.9894	0.9925
Logistic Regr	Entire data set	6.01	0.9938	0.9968	0.9908	0.9938
	Cross-validation	3.13	0.9954	0.9954	0.9954	0.9954
Random Forest	Entire data set	0.82	0.9972	0.9984	0.9960	0.9972
	Cross-validation	0.60	0.9976	0.9972	0.9981	0.9976
AdaBoost	Entire data set	26.26	0.9868	0.9959	0.9776	0.9867
	Cross-validation	17.88	0.9956	0.9965	0.9947	0.9956

Figure 3: Results from using various methods after performing feature selection

“unsubscribe”, “list”, “bounce”, “subject”, and “mailto”. This suggests that a possible extension is examining these email headers more closely. Two of our features are actually “spam” and “spamasassin”, suggesting that these emails have already been classified at least once or are announcing themselves as “not-spam”. This may have impacted our performance on this data set.

5.5 False negatives versus false positives

For the problem of spam classification, it’s better to have false negatives than false positives. This is because a user can manually specify that an email is spam, but they are unlikely to explore their “spam” folder. Therefore, non-spam emails classified as spam are likely to be missed entirely; this is highly undesirable. In general, the added hassle of having to deal with an occasional spam email outweighs the cost of missing an important email.

5.6 Hard cases to classify

We considered an example “hard” to classify if it was misclassified by more than one classifier. Hard false positives were rare, but appear to mostly be emails sent to mailing lists.

The only cases that were misclassified by all of our classifiers were false negatives. Hard examples included emails whose entire bodies consisted of random strings of letters (commonly text representations of images). Because we used a bag-of-words representation, it would treat these long strings as unique. Many other examples were very short emails. It makes sense that these might be misclassified because there’s just not that much content to work with. Finally, one spam email was written entirely in German, which the classifiers did not catch because most, if not all, of the other emails in this data set were written in English.

6 Conclusion and possible extensions

For the problem of spam classification, logistic regression seems to be the best choice to use of the five methods we explored. It had extremely high accuracy, precision, and recall and also had reasonable running time. Furthermore, its running time scales sublinearly with respect to the number of features. AdaBoost is not a good choice for this problem due to its large running time and its lack of increased performance relative to other possibilities.

Feature selection presents a tradeoff between correctness and computational time, but correctness suffers by a far smaller margin than computational time is benefited. In time-sensitive situations, using feature selection would definitely be preferable; in general, feature selection is probably still preferable.

We feel that using a different model to represent the emails’ content would be an interesting and potentially useful extension. While the bag-of-words model was certainly effective, many features were lost; in particular, we feel that things such as word order, capitalization, and punctuation are especially important in language and that their exclusion may have negatively impacted performance.

216 To elaborate on the above points, word order is important because it encodes meaning and context
217 of sentences—single words on their own may be ambiguous. Capitalization also matters, as emails
218 in all capitals, for example, are probably more likely to be spam. Punctuation also matters, because
219 emails with punctuation are more likely to have proper grammar, and correct grammar intuitively
220 seems indicative of non-spam (or, at least non-computer generated) emails.

221 One other feature is looking for attachments on files and possibly also looking at their types/file
222 extensions. This would help solve the issue we ran into with image attachments that ended up being
223 spam but were missed by our classifier.

224 It also may be beneficial to compare the words we get to actual English words. This would help
225 remedy the issue with missing spam emails that just consisted of long strings of random letters or
226 that were written in other languages.

227 Another possible extension is using a different data set. While our classifier performed very well on
228 this particular data set, that performance might not necessarily hold for use on other data sets. This
229 is because the set itself might have some trait that's highly indicative of spam versus not-spam that
230 is not indicative of or present in the population of emails as a whole. It would be helpful to use a
231 classifier trained on one set to test a different email corpus.
